# Convolution without Multiplication: A General Speed Up Strategy for CNN

Anonymous CVPR submission

Paper ID 2175

# **Abstract**

Convolutional Neural Networks (CNN) have achieved great success in many computer vision tasks. Due to the fact that most existing CNN models are computationally expensive, it is difficult to deploy these models on mobile or other low-cost devices with limited power budgets. Therefore, CNN model compression and acceleration becomes a hot research topic in deep learning area. Typical schemes including parameter pruning and sharing, low-rank factorization, compact convolutional filters and knowledge distillation. The purpose of these methods is to speed up the algorithm without significantly decreasing the accuracy. To this end, we propose a general accelerate scheme, where the floating point multiplication is replaced by integer addition. The motivation is based on the fact that every floating point can be replaced by the summation of a exponential series. Therefore the multiplication between two floating points can be converted to the addition among exponential. In the section of experiments, we directly apply the proposed scheme to AlexNet, VGG, ResNet for image classification, and Faster-RCNN for object detction. The results acquired from ImageNet and PASCAL VOC show that the proposed quantized scheme has promising performance, even with only one item of exponential. We also analyze the efficiency on main stream FPGA, which show the proposed quantized scheme can achieve more than 20× acceleration with only slight accuracy loss.

#### 1. Introduction

Deep neural networks are becoming the preferred tool in many machine learning and computer vision applications. However, with networks going deeper, the number of parameters in a network becomes larger. Typically, mainstream deep networks always have millions or even billions of parameters, which make deploying a deep network on a small device more difficult than before. On the other hand, there is an increasing demand for deploying deep CNN models in cell phone and other wearable devices

160 such as FPGA. Therefore, reduce the storage and the 161 computational cost of CNN becomes a critical task. 162

In recent years, much work has been done to compress, 163 or to accelerate the feed forward operations in CNNs. In [2], 164 Cheng et. al. classified these approaches into four categories. Which are respectively as parameter pruning and sharing, low-rank factorization, transfer/compact 167 convolutional filters, and knowledge distillation. Parameter pruning and sharing focus on remove redundant and 168 unimportant parameters. Low-rank factorization employed 169 matrix decomposition to measure the informative degree of 170 each parameter. The compact convolutional filters aim at 171 constructing efficient structural filters to reduce the storage. 172 The knowledge distillation methods try to learn a distilled 173 174 model to reproduce the output of a large network.

Although these methods have achieved great progress 175 in the past years, each scheme still has some issues that are 176 hard to solve. For example, the accuracy of binary or 177 quantized nets may decay when dealing with large CNNs. 178 Pruning scheme require manual setup of sensitivity for 179 layers. Low-rank factorization needs approximation layer 180 by layer, and thus is difficult to perform global parameter 181 compression. Transfer/compact approaches are suitable for 182 wide/flat models rather than narrow/special architectures. 183 Knowledge distillation can only be applied to classification tasks with softmax loss function. In other words, general and simple speed up scheme with low accuracy loss is still an challenging task.

To this end, this paper introduce a novel speed up strategy that can be directly applied in each CNN with 188 floating point multiplication. The scheme is simple, 189 efficient without any training process. The basic idea is to 190 reduce the number of floating point operation in CNN. 191 Specifically, we aims at finding an alternative scheme that 192 using integer addition to replace floating point 193 multiplication. We achieve such a target by replacing each 194 floating point with a exponential series. Then the 195 multiplication between two floating points is converted to 196 the addition among exponential. We demonstrate that our 197 quantized neural networks are comparable to standard full 198 precision networks while requiring less memory and 199 significantly reduce floating point multiplication.

The contribution of this paper is two-fold: First, we introduce a novel way of parameter quantization to

275

248

249

accelerate the feed foward operations of CNNs and show the results are comparable with original CNN models. Second, since most floating points in the network are replaced by short integers, the storage is also been reduced. To summarize, compared to each original CNN model, its quantized CNN model has faster feed forward speed, lower storage demand with almost no accuracy loss.

#### 2. Related Works

There has been a significant amount of work on accelerating and compressing CNNs. In order to point out the main contributions of the proposed quantized scheme, we first give a brief introduction of main stream accelerate schemes. Then we focus on analyzing the related works of quantization and binarization, which are mostly related to our method.

Firstly, low rank factorization and sparsity use matrix decomposition to evaluate the informative degree of each parameters in CNNs. Typical methods including separable 1D filters[2], low-rank approximation and clustering schemes[3], tensor decomposition schemes[4], which has 4.5× speedup with only 1% drop in accuracy, Canonical Polyadic (CP) decomposition[5], and low-rank tensor decomposition for training low-rank constrained CNNs[6], etc. Generally speaking, low-rank approaches are straightforward for model compression and acceleration.

Secondly, as for the compact convolutional filters, the basic idea is motivated by recent works in [2], which introduced the equivariant group theory. Following this trend, there are many works been proposed to build a convolutional layer from a set of base filters[32]-[17]. These methods can achieve competitive performance for wide/flat architectures but not narrow/special ones. On the other hand, compact filter for convolution can directly reduce the computation cost, such as decomposing 3×3 convolution into two 1×1 convolutions[25]. Similarly, SqueezeNet [29] proposed a scheme to replace 3×3 convolution with 1×1 convolution. Take AlexNet for example, SqueezeNet created a compact network with about 50 fewer parameters.

Thirdly, as for the parameter pruning and sharing scheme, a recent fashion trend is to prune redundant and non-informative weights in a pre-trained CNN model. Such as data-free pruning to remove redundant neurons[24], optimize the total number of parameters and operations in the entire network[10], HashedNets[1], soft weight-sharing [27], group sparsity constraint[14], structured sparsity regularizer [29], group-sparse regularizer[33], select and prune unimportant filters pruning based on L1-norm [16]. Note that most pruning criteria require manual setup of sensitivity for layers, which demands fine-tuning of the parameters and could be cumbersome for some application.

Finally, the quantization and binarization schemes aim at compressing the original network by reducing the number of bits required to represent each weight. This strategy is the most related to our approach. Among all the 250 network quantization algorithms, clustering-based scalar 251 quantization is the most widely used[7][31]. In [28], the 252 floating point is been converted to 8-bit quantization, which 253 results in significant speed-up with slight loss of accuracy. 254 Similarly, [8] proposed a 16-bit fixed-point representation 255 based CNN training, which significantly reduced memory 256 usage and floating point operations. In particular, recent 257 trends show that the combination of different schemes 258 achieved state-of-the-art performance, such as the method 259 proposed in [9]. The algorithm first pruned unimportant 260 connections and only retrained sparse connections. 261 Consequently, weight sharing based on Huffman coding is used to the quantized weights. The network is then 263 re-trained with remaining sparse connections. As for the 264 binarization scheme, there are also many works that directly train CNNs with binary weights. Typical works 265 include BinaryConnect [5], BinaryNet [4] and XNOR 266 Networks [19]. The main purpose is to directly learn binary <sup>267</sup> weights during the training process. In addition, [18] 268 showed that networks trained with back propogation are 269 robust against specific weight distortions, including binary 270 weights. one of the disadvantage is that the accuracy of 271 binarization network always significantly lower than its 272 original model, especially targeting with large CNNs. 273

#### 3. The Motivation

In order to make things clearer, we'll show our 276 motivation from two experiments. We found a fact that 277 slight changes of the parameters in a deep convolutional 278 neural networkmay not influence the discriminative ability 279 of features extracted via the network.

The first experiment focuses on evaluating the 281 differences between original CNN and rectified CNN. A 282 rectified CNN is generated from a typical CNN via a 283 quantification process. Particularly, we retain several 284 different digits after the decimal point of the convolutional 285 parameters during the process of parameter quantification 286 in original CNN. As shown in Table 1, we test three widely 287 used CNN models for image classification in ImageNet. In 288 the first row, the results of original CNNs are regarded as 289 the baseline, including AlexNet[13], VGG[23], and ResNet[11]. On the other hand, the rest 10 rows show the classification results that obtained from the quantized CNN. Specifically, the bold numbers numbers denoted the results <sup>292</sup> that are identical with baseline, where the red numbers 293 show that the quantized parameters perform better than 294 baseline. On can see that when we hold two digits after the 295 decimal point of the convolutional parameters, the results 296 are very close to original CNNs. In addition, if we only save 297 two digits after the decimal point, the results are almost 298 identical with the original CNNs. Specially, in ResNet50, 299 the quantized results are even better than the original network. Therefore, we can remark this phenomenon as follow:

**Table 1**. The performance of digit-quantized models for image classification

	VGG16		ResNet50		Alexnet	
	top1	top5	top1	top5	top1	top5
Original	70.956	89.9161	75.102	92.2002	56.8	79.946
1-digit	0.1	0.526	0.1	0.5	0.114	0.522
2-digits	69.354	88.908	73.6499	91.3502	56.202	79.636
3-digits	70.918	89.8981	75.202	92.2122	56.704	79.904
4-digits	70.948	89.9261	75.224	92.1782	56.802	79.958
5-digits	70.952	89.9161	75.212	92.1662	56.802	79.946
6-digits	70.956	89.9161	75.218	92.1662	56.8	79.946
7-digits	70.956	89.9161	75.218	92.1682	56.8	79.946
8-digits	70.956	89.9161	75.216	92.1682	56.8	79.946
9-digits	70.956	89.9161	75.216	92.1682	56.8	79.946
10-digits	70.956	89.9161	75.216	92.1682	56.8	79.946

**Remark 1:** Slight changes of the CNN parameters do not severely influence the performance. Specially, only three digits after the decimal point are important in CNNs. Namely, the digits after the first three digits in each parameter is not essential.

According to remark 1, slight changes of the parameters in a convolutional template do not influence the performance of CNN. Since the main purpose of our method is to convert the multiplication into addition, we then try to convert the convulutional parameters into the accumulations of exponential series. Theorem 1 explains that the combination can approximate any floating point with arbitrary precision.

**Theorem 1:** Given a floating point C in [-1, 1] and  $0 < a \le 2$ , for any  $\varepsilon > 0$ , there exists an integer K, a negative integer serial  $x_i$  (i = 0, -1, -2, ...), and a binary variable  $\delta_i \in \{-1, +1\}$  which satisfying the following equation:

$$\mid C - \sum_{i=1}^{K} \delta_i a^{x_i} \mid \leq \varepsilon \tag{1}$$

**Proof.** We use a strategy of greedy search to proof this theorem. Without loss of generality, let C>0. According to the definition of C, there exists a negative integer  $m_1 < 0$  that satisfies  $a^{m_1} \le C \le a^{m_1+1}$ . Let

that satisfies 
$$a^{m_1} \le C \le a^{m_1+1}$$
. Let 
$$x_1 = \begin{cases} m_1, & |C - a^{m_1}| \le |C - a^{m_1+1}| \\ m_1 + 1, & \text{otherwise} \end{cases},$$

then we have

$$C = \begin{cases} a^{x_1} + r_1, x_1 = m_1 \\ a^{x_1} - r_1, x_1 = m_1 + 1 \end{cases}.$$

The residual is denoted as  $r_1 = \min\{|C - a^{m_1}|, |C - a^{m_1+1}|\}$ . Likewise, there exists a negative integer  $m_2$  that satisfying  $a^{m_2} < r_1 < a^{m_2+1}$ . Also the residual can be derived as  $r_2 = \min\{|r_1 - a^{m_2}|, |r_1 - a^{m_2+1}|\}$ . The rest can be done in the same manner. Namely, we can deduce a residual sequence  $r_1, r_2, ..., r_n, ...$ . Note that the residual  $r_i$  is equal to  $r_{i-1}$  subtracts a positive number. As a consequent,  $r_1, r_2, ..., r_n, ...$  is a monotonically decreasing sequence.

On the other hand, given a  $\leq 2$ , we have  $\frac{364}{364}$   $r_i \leq \frac{a^{m_i+1}-a^{m_i}}{2} \leq \frac{a^{m_i}(a-1)}{2} \leq \frac{a^{m_i}}{2}$ , which means that each  $\frac{365}{366}$ 

 $r_i$  falls in different intervals. In other words, with the 367 increase of m,  $r_i$  converge to 0. Therefore, for any  $\varepsilon>0$ , there 368 exists an integer K, for any  $i \ge K$ , we have  $r_i \le \varepsilon$ . According 369 to the definition of  $r_i$  and  $x_i$ , the residual sequence 370

$$x_1, x_2, ..., x_n, ...$$
 satisfies  $|C - \sum_{i=1}^K \delta_i a^{x_i}| \le \varepsilon$ .

Theorem 1 shows that multiplication of floating points 373 can be converted into exponential (typically integer) 374 addition, with very slight accuracy loss. Recall the first 375 experiment, we show that when each convolutional 376 parameter is replaced by an approximated floating point, 377 the result is almost identical. Consequently, we'll explain 378 how to use exponential addition to construct a float point 379 approximating to the original parameter.

As shown in Figure 1, let  $x_i$  in  $\{0,-1,...,-N\}$ , item denotes the number of components that construct a floating point; the vertical axis presents the residual/error which is the difference between the original floating point and its approximated combination, which is acquired from the greedy search strategy; the horizontal axis denotes the range of input floating point, where the interval [0,1] is quantized as  $\{0,1,...,255\}$ ;  $\varepsilon = a^{-N}$  stands for the right endpoints of the first interval, which is closely related to the minimal error/residual. It is worth noting that smaller  $\varepsilon$  may results in larger look up table.

From Figure 1(a) to 1(d), one can see a common 393 phenomenon is that with the increase of the number of 393 items, the error will be drastically decreased. In particular, 394 when item=3, the fitting error is very small. This 395 phenomenon reveals that any floating point can be fitting 396 by a combination of exponential, given any accuracy. On 397 the other hand, with the decrease of  $\varepsilon$  is accompanied by 398 the increase of the range of N. In this situation, there exist 399 more smaller intervals/values for fitting, which may decrease the fitting error of exponential combination. Therefore, we can remark this phenomenon as follow:

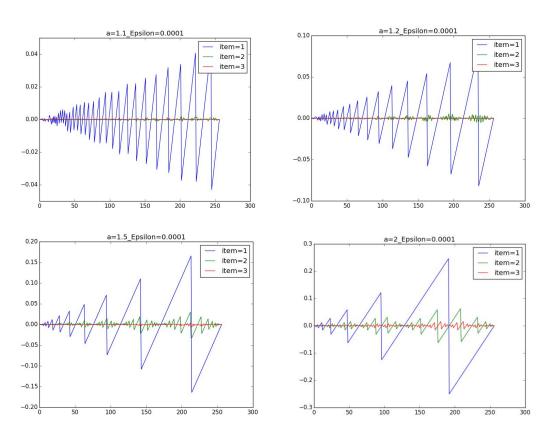

Figure 1. floating point fitting based on exponential addition

Remark 2: Each floating point can be fitted by a combination of exponential, then the operation of multiplication can be converted to addition. Given any small fitting error  $\varepsilon$ , there exists a combination that fits the original floating point with the residual smaller than  $\varepsilon$ .

Based on remark 1 and remark 2, we show that CNNs are robust to slight parameter change, and any parameter can be replaced by a combination of exponential with arbitrary small fitting error. Therefore, we can make a conjecture, given as follows:

Conjecture 1: Given any CNN, each parameter can be replaced by a accumulation of exponential. Then the multiplication operation can be converted to exponential addition. Specially, there exists a combination of exponential that satisfying any fitting error.

If conjecture 1 is correct, then all the multiplication operations in CNN can be replaced by integer addition. This strategy may drastically improve the efficiency of CNN, which allows CNNs deploy on cheap devices.

# 4. Transfer Multiplication to Exponential Addition

# 4.1. The principle of converting multiplication of floating point to integer addition

The basic idea of our speed up strategy is to convert

floating point multiplication to integer addition. Typically, 478 a floating point C can be approximated by accumulation of 479 a sequence of exponential, given as the following equation. 480

$$C \approx \sum_{i=1}^{\Lambda} a^{x_i} \tag{2}$$

For example, given N=2, the multiplication between to  $\frac{483}{1}$ float values becomes:

$$C^{1} \cdot C^{2} = (a^{x_{1}^{1}} + a^{x_{2}^{1}})(a^{x_{1}^{2}} + a^{x_{2}^{2}})$$

$$= a^{x_{1}^{1} + x_{1}^{2}} + a^{x_{1}^{1} + x_{2}^{2}} + a^{x_{2}^{1} + x_{1}^{2}} + a^{x_{2}^{1} + x_{2}^{2}}$$

$$(3) 486$$

$$487$$

In particular, when N=1, the multiplication can be 488 directly transfer to only one addition operation:

$$C^{1} \cdot C^{2} = (a^{x_{1}^{1}})(a^{x_{1}^{2}}) = a^{x_{1}^{1} + x_{1}^{2}}$$
(4) 490

Actually, in the section of experiments, we'll show 491 that N=1 with small value of a is a good trade off between 492computational cost and accuracy lost. Since this strategy 493 provide a general method to replace floating point 494 multiplication, it can be easily generalized to all 495 convolutional neural network. 

# 4.2. The construction of look up tables

Given an input floating point, the purpose of look up table is to provide fast index of its related exponential. For example, when we dealing with a 3×3 template, the target is

501

converted to the addition of 9 exponentials. We handle this problem by substituting the 9 exponentials with floating points. The fastest method is to acquire the 9 floating points from a look up table. We denote this look up table as exponential-real, which provides floating points given any exponential. Consequently, when we accumulate the 9 floating points, the result should be convert to exponential to the next layer. Hence the second look up table, named as real-exponential, should be constructed to give fast index of exponential combination given any floating point.

Algorithm 1. The greedy strategy for constructing real-exponential look up table

**Input**: The number of items K; the base of exponential a;  $\varepsilon$ ; the quantized factor M.

**Output**: The real-exponential look up table  $L_2$ .

- 1. Generate the floating point sequence  $a^0$ ,  $a^1$ ,  $a^2$ , ...,  $a^N$ , where  $N = \log_a \varepsilon$ .
- quantized intervals  $\left[\frac{m}{M}, \frac{m+1}{M}\right]$ , 2. Construct  $m=\{0,1,...,M-1\}$  according to quantized factor M.
- 3. **foreach** quantized interval  $\left[\frac{m}{M}, \frac{m+1}{M}\right]$  {

```
r_1 = \frac{m}{M};
5.
       for (i = 1: K)
6.
          r_{i+1}=MaxNum;
7.
          for (j = 0: N) {
8.
               tmp = abs(r_i - a^j);
9.
               if (tmp < r_{i+1}){
10.
                 r_{i+1}=tmp; C[i]=j;
                }//endif
11.
12.
            }//endfor
13.
            L[m][i] = C[i]; // Update look up table
14.
         }//endfor
15. \}//endfor
```

Obviously, the length of real-exponential look up table is equal to the range of N. Then each floating point in the look up table is directly derived from the item. Namely,  $L_1[i]=a^i$ ,  $i=\{-1, -2, ..., -N\}$ . As for the real-exponential look up table, we use a greedy scheme to establish the mapping between a floating point and it corresponding exponential. As shown in Algorithm 1, for each floating point falls in the

quantized interval  $\left[\frac{m}{M}, \frac{m+1}{M}\right]$ , we aims at giving the

related exponential from the look up table. Since slight changes of the value of parameter in CNN doesn't influence the performance of the network, we then provide the same integer combination for each floating point in

 $\left[\frac{m}{M}, \frac{m+1}{M}\right]$ . Suppose the combination has *K* items, then the

the greedy scheme is performed as the process which is mentioned in Theorem 1. Details of the algorithm for constructing real-exponential look up table is given in Algorithm 1. Since the two look up tables are all built off-line, the constructing process doesn't influence the 550 efficiency of the whole algorithm. 551 552

# 4.3. The pipeline of exponential addition in CNNs

554 In CNN, the multiplication operation exists in convolutional layer and fully connect layer. Since we use different strategies in the two layer, they are discussed separately. As for convolution operation layer, the kernels are expressed as the form of exponential. As a consequent, the pixel value of input image/feature map should be 559 converted to an integer, which is acquired from the 560 real-exponential look up table. For each pixel I(x,y) in the 561 input image/feature map, the convolution operation is 562 conducted according to the principle that mentioned in 563 subsection 4.1. Consequently, the result always contains 564 accumulation of several items. Then exponential-real look up table is used to covert each item to 566 a floating point. After finishing the summation in a 567 template, the result should be converted to a exponential 568 again via the real-exponential look up table. The details are 569 given in Algorithm 2. 570

**Algorithm 2.** The pipeline of convolution without multiplication 571 in a quantized network4.4 Time complexity analysis

**Input:** The number of items K; the base of exponential a;  $\varepsilon$ ; the quantized factor M; The look up tables  $L_1$  and  $L_2$ ; The quantized convolutional kernel C; The input feature map/image I; The target neural p.

**Output:** The output signal of p.

- 1. **if** (p in convolutional layers){//perform convolution
- 2. Select a template T, which is centered on p's coordinate, in p's former layer.
- Perform exponential addition to replace multiplication convolution operation K on T. Denote the results of exponential sequence as  $n_i$ , where  $i=\{1, 2, ...,$ scale(C)
- 4. for(i=1: scale(C)){
- 5. if  $(n_i > N)$  continue; // The related floating point is 0.
- 6.
- 7. search related floating point of  $n_i$  in the

exponential-real look up table. Accumulate the result.}//else

8. }//for

8. else  $\frac{1}{p}$  in fully connect layers

- Construct a table T3 to record the frequence of each exponential.
- 10 **for**(*j*=1: the number of neurals in former layer){
- Perform exponential addition: tmp= $Np+Nq_i$  // $q_i$ 11.
- denotes the jth neural in the former layer. 12. Perform frequence accumulation:  $T3[Np+Nq_i]++$
- 13. }//for
- 14. Locate all non-zero elements of T3 in the exponential-real look up table. Accumulate the result.
- 15. Convert the floating point to the related exponential via the real-exponential look up table. Output the result.

As for CNN with fully connected layer, each neural

649

connects with every neural in the former layer. Namely, if the former layer has M neurals, then there would be M multiplication operations to produce an output. In order to avoid visiting the look up table frequently, we replace the repetitive visiting with a histogram searching scheme. For example, in the VGG network, the number of neurals in the penultimate layer and the output layer are respectively as 4,096 and 1,000. In other words, each output neural connects with 4,096 neurals in the penultimate layer. It is worth noting that in our experiments, the range of N is typically smaller than 100, therefore there exists many repeated numbers. This phenomenon gives us a chance to drastically reduce the frequency of visiting look up tables. In view of this characteristic, we construct a table to store the frequency of each exponential been hit.

## 5. Experiments

# 5.1. Description of the experiments

In this section, we aim at evaluating the performance of the proposed accelerate scheme on mainstream models, including AlexNet[13], VGG[23], Residual Net[11] and Faster-RCNN[20]. The main task is to compare the accuracy loss between our quantized model and its original one. The detailed parameter settings in the implementation are given as follows. As for the task of image classification, we test all kinds of combinations, namely the base a, the minimal loss  $\varepsilon$ , the number of items K. Firstly, since a ranges from [1, 2], then a is respectively set as 1.1, 1.2, 1.5, 2.0. As for the minimal loss  $\varepsilon$ , it directly relates to the length of real-exponential look up table. We then choose  $\varepsilon$  $=\{10^{-4}, 10^{-3}, 10^{-2}, 0.02, 0.04\}$  to comprehensively evaluate the influence of  $\varepsilon$ . In addition, the number of items determine the length of exponential-real look up table in quantized models. Therefore, this parameter is a key factor in the proposed scheme, which makes a trade off between speed and accuracy. According to the experiment results shown in the section of motivation, the combination of three items has highest fitting accuracy compare its related floating point. Actually, our experiments show that the quantized models have almost identical performances with

two items. As a consequent, *K* is respectively been set as 1, 650 2. As for the task of object detection,  $\varepsilon$ , a, and the number 651 of items are respectively set as  $\varepsilon = \{10^{-4}, 10^{-3}, 10^{-2}, 0.05\}$ , 652  $a = \{1.1, 1.2, 1.5, 2.0\}$ , and item= $\{1, 2\}$ .

699

Moreover, in order to evaluate the efficiency of the 654 proposed method, some metrics have been employed such 655 as top1 and top5 in the task of image classification, and 656 mAP in the task of object detection. The results acquired 657 from original convolutional networks are regarded as the 658 baseline.

# 5.2. Image Classification

The first experiment is to evaluate the performance of 662 our strategy on the image classification task. Since  $\varepsilon$  is a 663 key parameter of the proposed scheme, the experiment then 664 focuses on the accuracy loss with scaling the value of  $\varepsilon$ .

Firstly, we try to test the performance of quantized 666 AlexNet, VGG, and ResNet with small value of  $\varepsilon$ . For 667 example,  $\varepsilon=10^{-4}$  means the minimal interval in the 668 quantized model is [0, 10<sup>-4</sup>]. As mentioned before, the 669 length of exponential-real look up table is  $N=-\log_a \varepsilon$ . Table 670 2 shows the results of three quantized models with  $\varepsilon=10^{-4}$ . 671 One can easily see that when we choose small value of a, 672for example a=1.1 or a=1.2, the number of item doesn't  $\frac{672}{673}$ influence the classification accuracy. In particular, some quantized models even outperform the original model. For example, when a=1.1, item=2, and a=1.2, item=2, the top1 675 and top5 in quantized VGG, and top1 in quantized 676 ResNet50 are all better than the original model. This 677 phenomenon reveals the fact that small value of a leads to 678small quantized intervals near to 1, which needs less item to 679 fit floating points near to 1. Therefore, the item value is not 680 a crucial factor, since the quantized models only have slight 681 accuracy loss in most cases.

On the other hand, when a has larger values, the length 683 of intervals varies greatly. As is shown in Fig.1, when a=2 684 with item =1, the values near 1 would has larger residual 685 than the result with smaller a. As a consequent, the 686 quantized model performs worse than their original models. 687 For example, when  $\varepsilon$ =10<sup>-4</sup> with a=2.0 and item=1, the 688 accuracy are drastically dropped.

The same conclusions can be drawn in Table 3 and Table 4, where the combination of small a with larger number of item has better performance. Specially, when  $\varepsilon=10^{-3}$ , VGG with a=1.1 or 1.2, item=2, ResNet and AlexNet with a=1.1, item=2 are all better than original models. Note that item=1 means the each floating point multiplication can be directly converted on only one integer addition. Although Fig.1 denotes that the fitting error with item=1 is large, the results from Table 2 to Table 4 show that the performances of quantized models only have slight

accuracy loss with small values of *a*. There are two reasons 772 can explain this phenomenon. First, deeper neural networks have larger number of parameters, whose performances are 773 more robust to slight parameter changes. Second, most 774 parameters in DNNs are distributed around 0. Therefore, 775 even the parameters near 1 are replaced with large residual, 776 the results are still promising. From the viewpoint of 777 quantized scheme, these two factors explain the reasons 778 why the proposed quantized strategy can accelerate the feed 779 forward operations with promising performance.

Secondly, according to the definition of look up table length  $N=-\log_a \varepsilon$ , once we increase the value of  $\varepsilon$ , the length of exponential-real look up table will be shorten. However, the fitting error between the combination of exponential and its original floating point would be increased. Table 5 and table 6 show the results of  $\varepsilon$ =0.02 and  $\varepsilon$ =0.04 . One can see that when  $\varepsilon$ =0.02 with  $\alpha$ =1.1or  $\alpha$ =1.2, the quantized models still have good performances. Nevertheless, when a>1.5, the performances are drastically dropped. Table 6 also has the same property. In other words, smaller  $\varepsilon$  means most floating points are hard to be replaced by a exponential sequence with small residual. Therefore, the parameters in each quantized model are greatly different with the original one. As a consequent, the performances may dropped drastically.

Based on the experiment results mentioned above, we can draw a conclusion that  $\varepsilon$ , a, item are all key parameters in the proposed scheme, which makes trade off between speed and accuracy. Smaller value of  $\varepsilon$  means larger chance to select a exponential sequence with slight residual to replace a floating point. On the other hand, larger value of a means shorten look up table and faster speed, while the number of exponential combinations would be reduced, which may influence the performance. Last but not the least, the number of items directly relate to the scale of fitting error. More items mean less residuals, resulting in higher computational complexity during the process of floating point fitting and look up table searching.

## 5.3. Object Detection

In the second experiment, we aim at evaluating the proposed quantized scheme on the task of object detection. To this end, the Faster R-CNN, one of the most widely used detection framework, has been selected. Since our target is to evaluate the total performance of our strategy, we only concern on the Mean Average Precision (mAP) of the detect results. The experiments are conducted on PASCAL VOC 2012, which is widely used in object detection task. In particular, the result of original Faster R-CNN (mAP=69.45) is set as the baseline.

Table 7 Performances of quantized Faster R-CNN model on PASCAL VOC 2012 with different parameters setting

Quantized model	ε=10-4	ε=10 <sup>-3</sup>	ε=10 <sup>-2</sup>	ε=0.05
<i>a</i> =1.1, item=1	68.53	68.53	68.21	61.81
a=1.1, item=2	69.18	68.90	68.59	61.89
a=1.2, item=1	67.74	67.74	67.98	59.11
a=1.2, item=2	69.00	68.85	68.93	60.42
a=1.5, item=1	61.20	61.20	60.40	40.11
a=1.5, item=2	68.59	68.79	68.79	49.35
a=2.0, item=1	44.32	44.32	44.20	23.06
a=2.0, item=2	68.09	68.09	68.00	25.24

Table 7 shows the results of the proposed quantized method. One can see that when  $\varepsilon$  has small value, such as  $\varepsilon=10^{-4}$ , the results are comparable with the baseline, except a=2.0 with item=1. In other words, the performance of 850 quantized Faster R-CNN doesn't drop with small value of  $\varepsilon$ . 851 Noteworthy that this phenomenon exists in almost all 852 combinations of a and item. In particular, when item=1 853 with  $\varepsilon \le 10^{-2}$  and a=1.2, the mAP still very close to the 854 baseline, which means that each floating points operations 855 in Faster R-CNN can also be replaced by only one 856 exponential addition without slight mAP loss. However, 857 when we choose small value of  $\varepsilon$ , such as  $\varepsilon$ =0.05, the 858 performance drastically dropped. This phenomenon also 859 reveals the fact that most floating points in Faster R-CNN are also distributed around 0, which makes the fitting 861 residuals larger than that of small value of  $\varepsilon$ . And this is the 862 main reason why the DNN models decays with large  $\varepsilon$ . 863

#### 5.4. Acceleration analysis on FPGA

In order to show the feasibility of the proposed scheme, 866 we also evaluate the property of acceleration on FPGA. 867 Take Xilinx Vritex-7 for example, it is a state-of-the-art 868 FPGA system. If we optimize the use of computational 869 resources, our integer addition scheme approaching at least 870  $1289/d \times$  acceleration. Where d denotes the length of look up table. For example, if we choose the VGG model for the task of image classification, with  $\varepsilon=10^{-4}$ , a=1.2 and item=1, then the length of look up table is about 52. As a consequent, 874 the feed forward operations obtain more than 20× speed up. compare to the original VGG model. In particular, the accuracy loss of the quantized VGG model is less than 1%, which means that our scheme is suitable for deploying 877 878 CNNs on low cost devices.

# 6. Conclusions

In this paper, we present a novel and general speed up strategy for CNNs. The basic idea is to reduce the frequency of floating point multiplication in CNNs. Therefore, each floating point in the network is replaced by the summation of a exponential series. Then the 885 multiplication between two floating points can be converted 886 to the addition among exponential. Specially, we give a 887 brief description of how to convert floating point 888 multiplication to integer addition, which is the main 889 contribution of our work. Furthermore, we give a theorem 890 to guarantee the range of fitting residual. In the section of 891 experiments, the proposed scheme has been directly applied 892 to AlexNet, VGG, ResNet for image classification, and 803 Faster R-CNN for object detection. The results conducted 894 on ImageNet and PASCAL VOC show that the proposed 805 quantized scheme has promising performance. Namely, in 896 most CNNs each multiplication can be directly replaced by 897 only one addition operation with slight accuracy loss. These results mean that the proposed quantization scheme can be used in most CNNs, and the related quantized models can be easier deploy on mobile or other low-cost devices with limited power budgets, such as FPGA.
